

## MOLECULAR PHYLOGENETICS OF *ECHINOPSIS* (CACTACEAE): POLYPHYLY AT ALL LEVELS AND CONVERGENT EVOLUTION OF POLLINATION MODES AND GROWTH FORMS<sup>1</sup>

BORIS O. SCHLUMPERGER<sup>2</sup> AND SUSANNE S. RENNER

Systematic Botany and Mycology, University of Munich (LMU), Menzinger Str. 67 80638 Munich, Germany

- *Premise of the study:* In its current circumscription, *Echinopsis* with 100–150 species is one of the largest and morphologically most diverse genera of Cactaceae. This diversity and an absence of correlated characters have resulted in numerous attempts to subdivide *Echinopsis* into more homogeneous subgroups. To infer natural species groups in this alliance, we here provide a plastid phylogeny and use it to infer changes in growth form, pollination mode, and ploidy level.
- *Methods:* We sequenced 3800 nucleotides of chloroplast DNA from 162 plants representing 144 species and subspecies. The sample includes the type species of all genera close to, or included in, *Echinopsis* as well as a dense sample of other genera of the Trichocereeae and further outgroups. New and published chromosome counts were compiled and traced on the phylogeny, as were pollination modes and growth habits.
- *Key results:* A maximum likelihood phylogeny confirms that *Echinopsis* s.l. is not monophyletic nor are any of the previously recognized genera that have more than one species. Pollination mode and, to a lesser extent, growth habit are evolutionarily labile, and diploidy is the rule in *Echinopsis* s.l., with the few polyploids clustered in just a few clades.
- *Conclusions:* The use of evolutionary labile floral traits and growth habit has led to nonnatural classifications. Taxonomic realignments are required, but further study of less evolutionary labile traits suitable for circumscribing genera are needed. Surprisingly, polyploidy seems infrequent in the *Echinopsis* alliance and hybridization may thus be of minor relevance in the evolution of this clade.

**Key words:** Cactaceae; chromosome counts; *Echinopsis*; growth form evolution; phylogenetics; pollination modes; polyploidy; Trichocereeae.

Cactaceae comprise some 1870 species in 130 genera (Nyffeler and Eggli, 2010) and are estimated to have diversified since the mid-Tertiary, about 30 million years ago (Ma) (Hershkovitz and Zimmer, 1997). They are an important component of seasonally dry tropical and subtropical ecosystems, where their adaptations for water conservation and water storage permit them to survive even pronounced droughts. Different growth habits, such as columnar, globular, or barrel growth, may characterize larger species groups, but molecular-phylogenetic studies in Cactaceae have rarely addressed the evolution of growth forms (but see Hernández-Hernández et al., 2011). Similarly, floral characters and pollinator affiliation in cacti have rarely been studied in an evolutionary context, mostly for lack of large phylogenies and fieldwork on pollination biology. That polyploidy relates to diversification has been suggested for several clades of cacti (Remski, 1954; Pinkava et al., 1985;

Cota and Philbrick, 1994; Cota and Wallace, 1995; Pinkava, 2002; Negrón-Ortiz, 2007), but again the evidence is limited due to a paucity of chromosome counts for species (or clades) of known relationships. Nevertheless, it is thought that polyploidy may be an important speciation mechanism in some Cactaceae (Negrón-Ortiz, 2007; Arakaki et al., 2007, and citations therein).

One of the least understood groups of cacti is the *Echinopsis* alliance, which includes 100–150 species that exhibit a great diversity in architecture and that variously are pollinated by bees, hummingbirds, or sphingids (Schlumpberger and Badano, 2005; Schlumpberger and Raguso, 2008; Schlumpberger et al., 2009; Walter, 2010; Ortega-Baes et al., 2011). The *Echinopsis* alliance belongs in the Trichocereeae (Anderson, 2001, 2005; Hunt, 2006) or Trichocereinae of a more broadly circumscribed Cereeae (Nyffeler and Eggli, 2010). The species occur from southeastern Brazil to the coast of Chile and north to northern Ecuador, with a center of species diversity in the eastern Andes of northern Argentina and Bolivia. With more than 500 species names, *Echinopsis* is taxonomically problematic and much in need of study of natural intraspecific variation as well as molecular phylogenetic work (Anderson, 2001; Hunt, 2006; Nyffeler and Eggli, 2010). In the broad circumscription of Hunt (2006), *Echinopsis* includes 18 genera, including the well-known and species-rich *Lobivia* Britton & Rose and *Trichocereus* Riccob. Because of the problematic generic boundaries, recent studies continue to lump these difficult genera “to be conservative” (Arakaki et al., 2011: p. 8383). The 18 genera included in *Echinopsis* by Hunt initially were created based on traits, such as diurnal vs. nocturnal flowering, flower color, and growth form, i.e., globular vs. columnar: Thus, the name *Lobivia*

<sup>1</sup>Manuscript received 22 June 2011; revision accepted 3 July 2012.

The authors thank Stephan Beck, Grischa Brokamp, Andrea Cocucci, Roberto Kiesling, Alicia Sérsic, and Sandra Sieffken for help during fieldwork; Urs Eggli, Hans Frohning, Ralf Hillmann, Cyril Hunkeler, Martin Lowry, Jörg Piltz, Eberhard Scholz, Daniel Schweich, and Matthias Uhlig for plant material; and Martina Silber for GenBank annotations and submission of all sequences. Verena Beyer and Kerstin Schuster produced some of the sequences as part of their research at the University of Munich. The project was supported by DFG grants SCHL 1820/1-1 and 1820/1-2 and the Alexander von Humboldt Foundation.

<sup>2</sup>Author for correspondence (e-mail: boris.schlumpberger@hannover-stadt.de); present address: Herrenhausen Gardens, Herrenhäuser Str. 4, 30419 Hannover, Germany; phone: +49-511-168-47575,

applied to mostly globular cacti from the medium to high Andes with short, diurnal flowers of various colors; *Trichocereus* was used for mostly columnar, sometimes tree-like cacti with flowers that are usually large, white, and nocturnal; and *Echinopsis* in the original sense applied to globular plants with white, funnel-shaped flowers of predominantly nocturnal anthesis. Species combining these characters were placed in separate genera, such as *Helianthocereus*, created for species of columnar habit, but with diurnal flowers (see Table 1 for a short history of *Echinopsis* taxonomy).

Here we present a densely sampled molecular phylogeny for *Echinopsis* that includes 144 species and subspecies, including the type species of all relevant generic names, as well as representatives of all genera in recent years assigned to the tribe Trichocereeae, again including relevant generic type species. To assess the role of chromosome number changes, we generated new counts for 37 selected taxa and added these to previous counts for a phylogenetically distributed sampling. We use these data to address the following questions: (1) Is *Echinopsis* in the broad sense monophyletic? (2) What is the level of variation of growth habit and pollination mode, characters that have been used to define clades in *Echinopsis* sensu lato? And (3) How common are ploidy changes in the *Echinopsis* alliance, and are they clustered in certain subclades, perhaps indicating a role for hybridization in the evolution of certain species groups.

## MATERIALS AND METHODS

**Taxon sampling**—Molecular phylogenies to date have included three to nine species of *Echinopsis* plus few of the potentially embedded related genera of Trichocereeae (Nyffeler, 2002; Ritz et al., 2007; Hernández-Hernández et al., 2011). We obtained tissue samples from 162 plants representing 31 genera, 129 species, 8 subspecies, and 2 varieties; 74 species belong to *Echinopsis* s.l., the remaining ones are species not previously assigned to *Echinopsis* (see Table 2 for taxonomic names and their authors, as well as information about generic type species). Our sample includes representatives of all nine infrageneric groups of *Echinopsis* defined by Friedrich and Glätsche (1983) and representatives of the 13 sections of *Lobivia* defined by Rausch (1985). We further included 54 species representing the 24 genera of the tribe Trichocereeae (Anderson, 2005), and part of the Browningiaeae-Cereeae-Trichocereeae (BCT) clade of Nyffeler (2002). For rooting, we chose *Neowerdermannia vorwerkii* from core Notocacteae, based on Nyffeler (2002).

Material was field-collected by the first author or obtained from documented material from public and private collections. All species identifications were made or confirmed by the first author. Vouchers are listed in Table 2.

TABLE 1. Major steps in the history of *Echinopsis* taxonomy.

**DNA extraction, amplification, sequencing, and alignments**—Samples were collected from floral or vegetative tissue and silica-dried. Total genomic DNA was extracted using the NucleoSpin extraction kit (Macherey-Nagel, Düren, Germany), following the manufacturer's protocol, but with an elongated lysis step over night at 4°C.

We amplified three noncoding chloroplast DNA regions using published standard primers: the *trnS-G* intergenic spacer (Hamilton, 1999), the *trnL* region (Taberlet et al., 1991), and the *rpl16* intron (Aasmussen, 1999). PCR reactions were performed in 25 µL reactions (1.25 µL DNA, 0.1 µL *Tag* polymerase, 0.8 µL primer (10 µL), 0.5 µL 1.5 mmol/L MgCl<sub>2</sub>, 4 µL 5× buffer, 4 µL 1.25 mmol/L dNTP, 0.25 µL BSA) as follows: initial denaturation was at 95°C for 5 min; followed by 35 cycles of 95°C for 30 s (denaturation), 48–55°C for 1 min (annealing) and 72°C for 2 min (elongation); and 72°C for 40 s (final extension). PCR reaction products were purified using the Wizard SV PCR clean-up kit (Promega GmbH, Mannheim, Germany). Sequencing reactions were performed with the Big Dye Terminator kit (Applied Biosystems, Warrington, UK), and cleaned with the Sephadex G-50 gel filtration system (Amersham, Uppsala, Sweden) using MultiScreen TM-HV membrane plates (Millipore, Bedford, Massachusetts, USA) according to the manufacturer's protocol. Reactions were run on an ABI 3100 Avant capillary sequencer. Sequences were edited and assembled using the program Sequencher 4.5 (Gene Codes, Ann Arbor, Michigan, USA). Sequences were aligned using Prank (Löytynoja and Goldman, 2005) and corrected by eye in the program MacClade 4.08 (Maddison and Maddison, 2003).

**Phylogenetic analyses**—Chloroplast partitions were first analyzed separately to check for possible contamination or mislabeling that might have led to incongruent topologies, and in the absence of statistically supported topological contradictions (defined as >70% maximum likelihood bootstrap support), all sequences were combined. Phylogenetic inference relied on maximum likelihood (ML) under the GTR + G model as implemented in the program RAxML BlackBox (Stamatakis et al., 2008, <http://phylobench.vital-it.ch/raxml-bb/>).

**Chromosome counts**—Root tips were collected from plants cultivated at the Munich Botanical Garden and immediately transferred to 2 mmol/L 8-hydroxyquinoline to arrest metaphases, then fixed in 3c:1 ethanol-acetic acid, and stored until use at -20°C. Chromosome spreads were obtained after hydrolysis in 0.5 N hydrochloric acid at 60°C for 10 min and staining with a saturated orcein-glacial acetic acid solution. Our sampling includes species from all groups (genera) embedded in *Echinopsis* or newly revealed as closely related by our molecular data.

**Pollination modes and growth forms**—All species sequenced were assigned to one or several pollinator groups (bee, hummingbird, bat, or sphingid) on the basis of either our own field observations or inferred from combinations of floral traits, such as anthesis time, floral bauplan (i.e., mostly shape and length of the hypanthium), and nectar production. For growth form, we assigned species to one of two types, globular growth or columnar growth.

## RESULTS

**Relative frequencies of changes in pollination mode, growth architecture, and chromosome number**—We generated 457 new chloroplast sequences (Table 2). The concatenated aligned matrix comprised 3866 nucleotides. Maximum likelihood analysis of these data yielded the tree shown in Fig. 1A and B, which also shows growth form (categorized as globular or columnar), pollination mode, and chromosome number. Inspection of the tree reveals many more changes in pollination modes than in growth form, and even though chromosome counts are not available for all species, polyploidy (tetraploidy) appears common in the *Oreocereus* clade and in *Weberbauerocephalus*, and rare elsewhere (Fig. 1, Table 3; more about chromosome numbers in the next section). Major clades were named using oldest available genus names.

A monophyletic *Echinopsis* would need to include *Acanthocalycium* Backeb., *Arthrocereus* A.Berger, *Cephalocleistocactus* F.Ritter, *Cleistocactus* Lem. (including *Borzicactus*

TABLE 2. Species and loci sequenced newly for this study, their sources and provenance, voucher informations, herbarium code, and GenBank accession numbers. Generic types are indicated (GT) and synonymous names are given where they are still widely used.

Notes: \* wild-collected, \*\* samples from cultivated plants of documented origin

Riccob.), *Denmoza* Britton & Rose, *Espostoa* Britton & Rose (including *Vatricania* Backeb.), *Haageocereus* Backeb., *Harrisia* Britton, *Matucana* Britton & Rose, *Mila* Britton & Rose, *Oreocereus* (A.Berger) Riccob., *Oroya* Britton & Rose, *Pygmaeocereus* H.Johnson & Backeb., *Rauhocereus* Backeb., *Samaipaticereus* Cárdenas, *Weberbauerocereus* Backeb., and *Yungasocereus* F.Ritter, all of which are part of a well-supported clade (100% bootstrap support) interspersed with species of *Echinopsis* (Fig. 1A, B). Species previously assigned to *Lobivia*, i.e., species with diurnal flowers, *Trichocereus*, i.e., columnar species, or *Echinopsis* s.str., i.e., globular species with funnel-shaped flowers of nocturnal anthesis, do not form clades. The genera *Espostoa*, *Cleistocactus* s.l. (i.e., sensu Hunt, 1999, 2006) and *Matucana* are polyphyletic (Fig. 1), and *Acanthocalycium* is paraphyletic since *Echinopsis leucantha* is embedded among its species. Our sampling also reveals a few taxonomic problems at the species level: thus, *E. aurea* is polyphyletic, with the isolated northernmost form (*E. aurea* var. *callochrysea*) close to *E. tubiflora*.

**Chromosome numbers**—Table 3 lists new chromosome counts for numerous *Echinopsis* (sub) species or varieties included in the phylogeny as well as for 11 outgroup species from eight genera. The basic chromosome number is  $2x = 22$ . We discovered six cases of tetraploidy of which two involve intraspecific variation between diploidy and tetraploidy. In

the *Helianthocereus* clade, tetraploids occurred in *E. thelegonoides* and *E. candicans* (Fig. 1B). In the *Lobivia* clade, we found diploids and tetraploids in *E. tiegeliana*, and in the *Oreocereus* clade we found tetraploids in *Espostoa* and *Oreocereus* itself (Fig. 1, Table 3). In *Rebutia* K.Schum., we found tetraploidy in a species previously assigned to *Mediolobivia* Backeb.

## DISCUSSION

We now address the main questions posed in this study, namely (1) Is *Echinopsis* in the broad sense monophyletic? (2) What is the level of plasticity of growth habit and pollination mode, characters that have been used to define clades in *Echinopsis* sensu lato? And (3) How common are ploidy changes in the *Echinopsis* alliance and are they clustered in certain subclades?

**Monophyly of *Echinopsis* sensu lato**—*Echinopsis* as circumscribed by Anderson (2001) or Hunt (2006) would become monophyletic with the inclusion of *Acanthocalycium* (part of *Echinopsis* in Hunt, 2006, but not in Anderson, 2001 and 2005), *Arthrocereus*, *Cephalocleistocactus*, *Cleistocactus* (including *Borzicactus*), *Denmoza*, *Espostoa* (including *Vatricania*), *Haageocereus*, *Harrisia*, *Matucana*, *Mila*, *Oreocereus*,

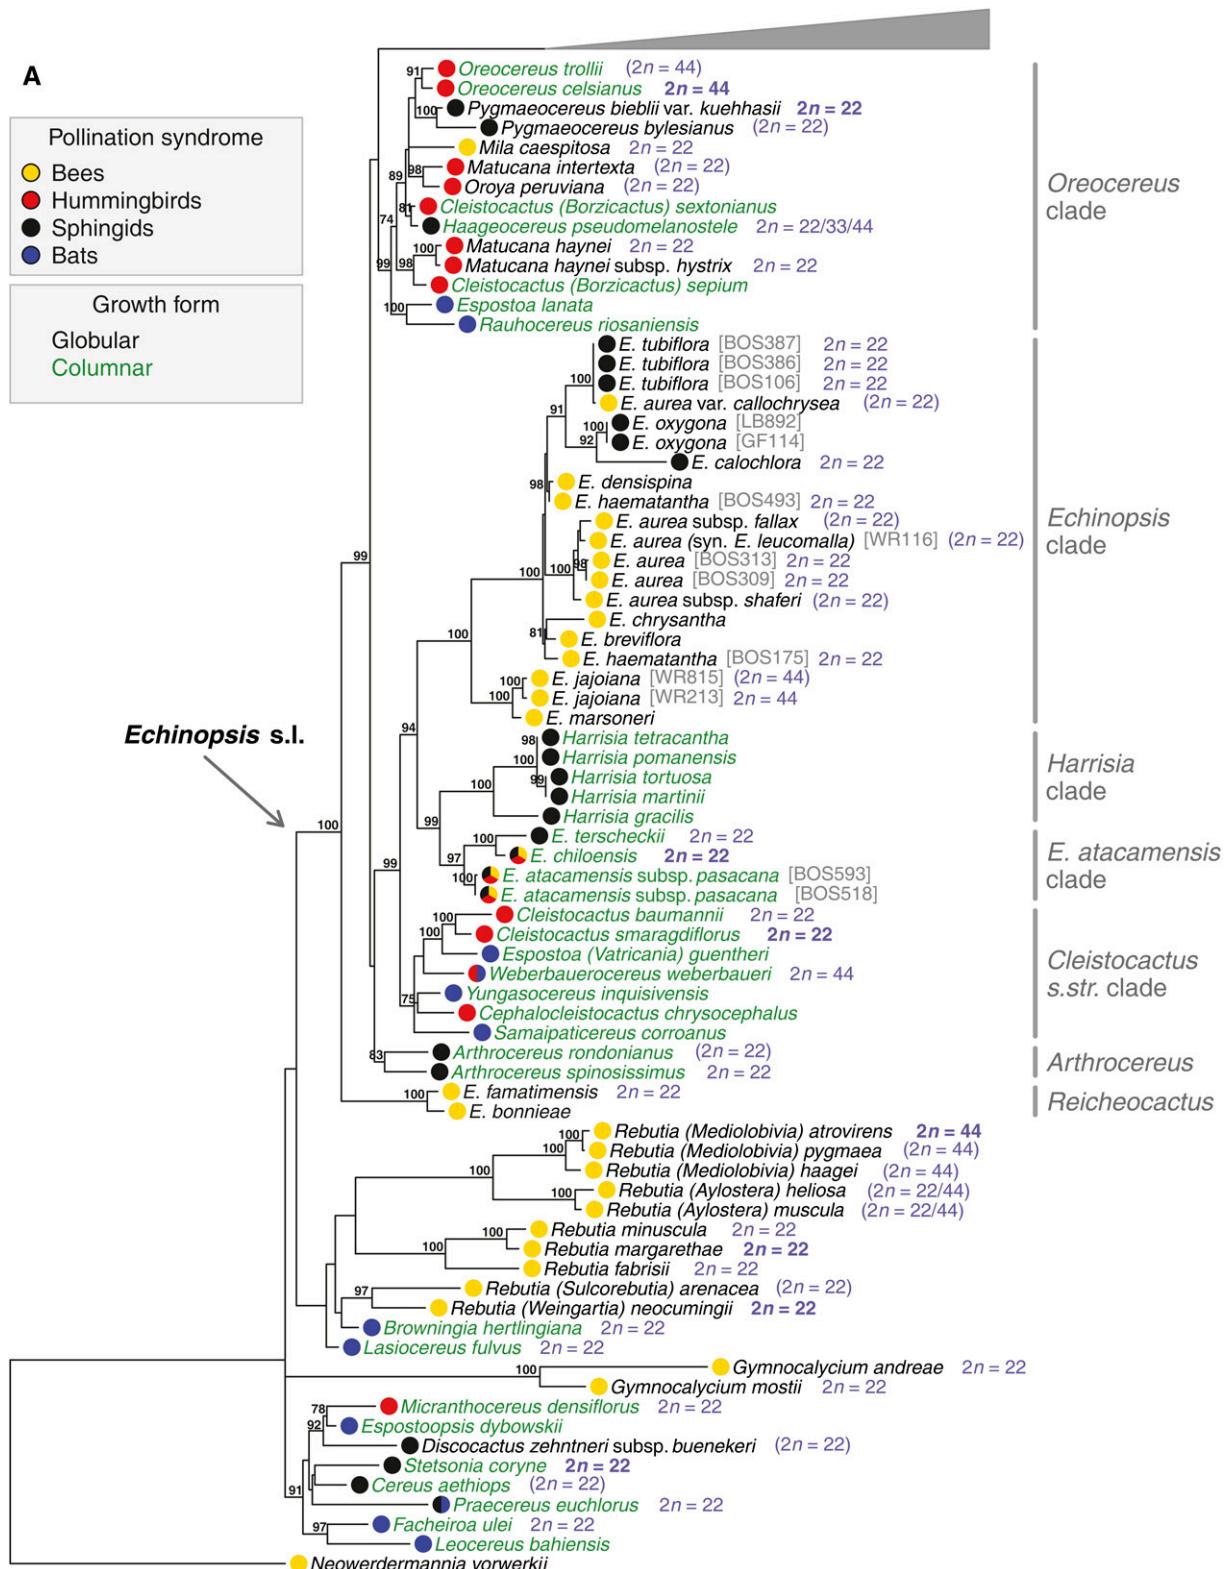

Fig. 1. (A, B). Maximum likelihood (ML) phylogram for 144 taxa of *Echinopsis* and relatives obtained from 3866 aligned nucleotides of chloroplast DNA. Numbers at nodes indicate ML bootstrap support >70% from 100 replicates. Known or putative pollinators are indicated by pie diagrams, with the color codes explained in the inset; sphingid-adapted taxa with bees as backup pollinators are treated as sphingid-pollinated. Growth form is indicated by different taxon name colors as explained in the inset. New or previously published chromosome counts are shown as follows: Bold numbers indicate counts that were made from the same plant as was sequenced; numbers in parentheses refer to counts made from a closely related taxon; the remaining numbers refer to counts from the same taxon but not the sequenced individual (see Table 2 for sources). Collection numbers behind plant names refer to vouchers cited in Table 1; they are given only for species represented by multiple accessions.

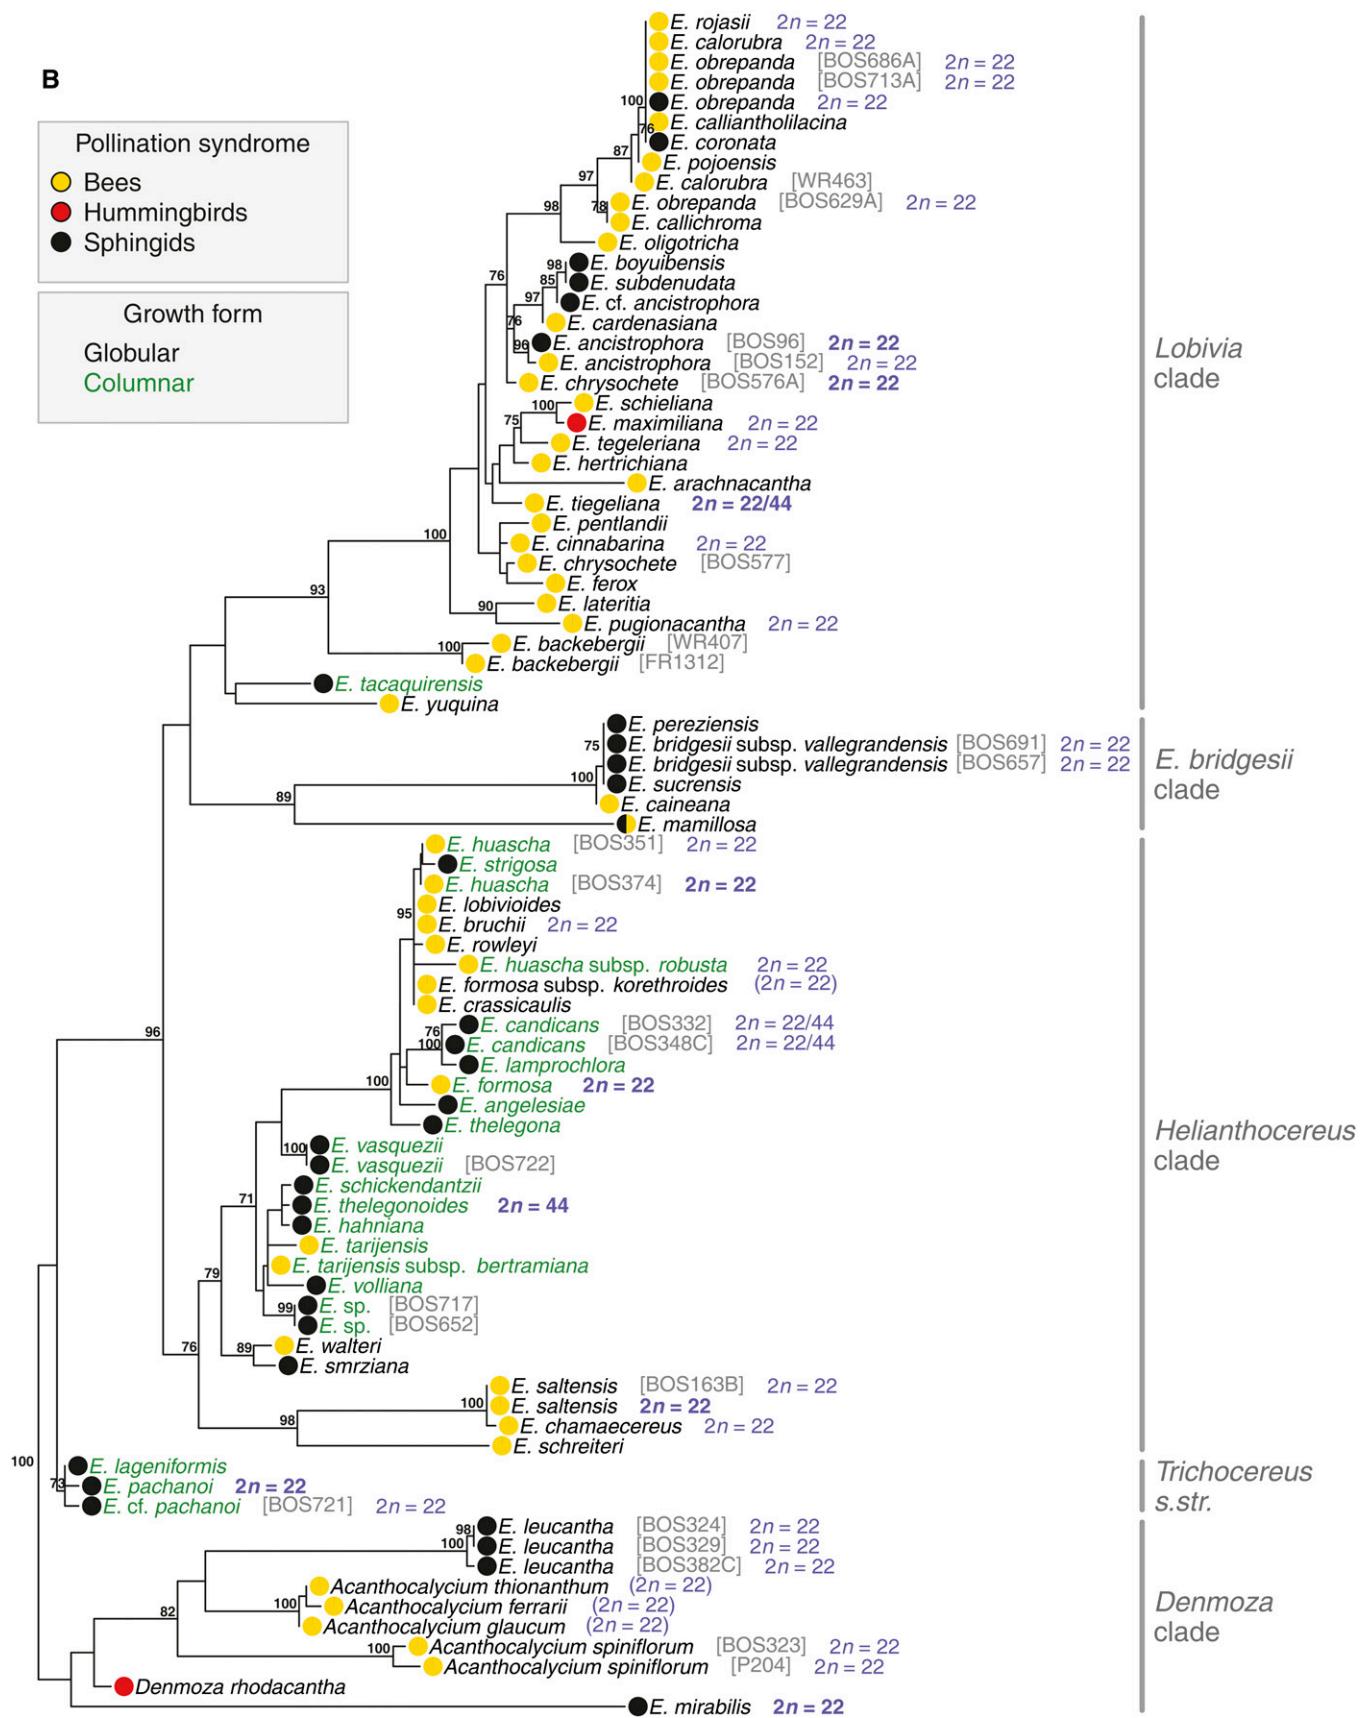

Fig. 1. Continued.

TABLE 3. Chromosome numbers in *Echinopsis* and related Trichocereeae. Authors for taxon names can be found in Table 1, except for taxa not sequenced for which they are listed here. Abbreviations: BGM—Botanical Garden Munich. Collectors' acronyms are BOS: B. O. Schlumpberger, DH: D. Herzog, ES: E. Scholz, FR: F. Ritter, GF: N. Gerloff, HJW: H. J. Wittau, HUN: C. Hunkeler, KK: K. Knižek, LB: L. Bercht, LK: L. Kunte, MN: M. Winberg, P: J. & B. Piltz, UE: U. Eggli, WR: W. Rausch, and many individual collections are also cited in Table 1. Details for those not cited there are available online under <http://ralph.cs.cf.ac.uk/cacti/fieldno.html>.

Fig. 2. Examples for convergent evolution in *Echinopsis*. Floral adaptation to hawkmoth pollination in *E. ancistrophora* (A, *Lobivia* clade) and *E. tubiflora* (B, *Echinopsis* s.str. clade) and columnar growth in *E. tarijensis* (C, *Helianthocereus* clade) and *E. atacamensis* subsp. *pasacana* (D, *E. atacamensis* clade).

*Oroya*, *Pygmaeocereus*, *Rauhocereus*, *Samaipaticereus*, *Weberbauercereus*, and *Yungasocereus*. Alternatively, *Echinopsis* will need to be divided into smaller, more homogeneous units, requiring the resurrection of generic names and transfers of species epithets. We now briefly discuss the main clades found in this study.

*Echinopsis* s.s. is well supported (100% bootstrap support; the type species is *E. oxygona*) and homogeneous in growth

form. Its sister group consists of the likewise well-supported *E. atacamensis* clade and the genus *Harrisia* (100% and 97% bootstrap, respectively, Fig. 1A), refuting suggestions that *Harrisia* might be part of the Hylocereeae (A. Areces-Mallea, personal communication, cited in Anderson, 2001) or the Echinocereeae (Barthlott and Hunt, 1993). Of the ca. 20 species of *Harrisia*, we sampled *H. gracilis* from the Caribbean and four species from central South America.

The *Cleistocactus* s.str. clade (Fig. 1A, 100% bootstrap) comprises the columnar cacti *Espositoa guentheri* (syn. *Vatricania*), *Samaipaticereus*, *Weberbaueroocereus*, *Yungasocereus*, *Cephalocleistocactus*, and *Cleistocactus*. Species formerly placed in *Borzicactus* but transferred to *Cleistocactus* (Hunt, 2006) turn out not to belong there but instead to the *Oreocereus* clade (Fig. 1A), and future studies will have to investigate if other species transferred to *Cleistocactus* from *Winterocereus* (syn. *Winteria* and *Hildewintera*) and *Bolivicereus* also instead belong to *Borzicactus*. Most species in the *Cleistocactus* clade are adapted to pollination by bats (*Espositoa*, *Samaipaticereus*, and *Yungasocereus*) or hummingbirds (*Cephalocleistocactus* and *Cleistocactus*), and *Weberbaueroocereus* species are visited, and apparently pollinated, by both bats and hummingbirds (Sahley, 1996). That *Espositoa* (*Vatricania*) *guentheri* is not grouping with *E. lanata*, the type species of *Espositoa*, fits with an anatomical study that found it to have “the greatest number of unusual features” among six species of *Espositoa* studied (Mauseth, 1999: p. 36). One of these unusual features, a two-layered hypodermis with clusters of columnar cells, resembles the hypodermis of *Cleistocactus strausii* and *Weberbaueroocereus albus*, which are related to species that group with *Espositoa* (*Vatricania*) *guentheri* in our study.

Next closest is the *Reicheocactus* clade (Fig. 1A). The relatively early-diverging species *E. famatimensis* and *E. bonnieae* have long troubled Cactaceae taxonomists. First described as *Echinocactus famatimensis* (Spegazzini, 1921), the former was subsequently transferred to *Rebutia* (Spegazzini, 1923) and *Lobivia* (Britton and Rose, 1919–1923), and in 1942 to the new genus *Reicheocactus* Backeb. (as *Reicheocactus pseudoreicheanus*). In recent years, it was usually included in *Echinopsis* (Anderson, 2001; Hunt 2006; but see Kiesling et al., 2001, who returned it to *Lobivia*). *Echinopsis bonnieae* likewise has been moved between *Lobivia* (as *Lobivia bonnieae* Halda & Horáček, 1999) and *Echinopsis*.

Another well-supported group is the *Oreocereus* clade (Fig. 1A, 99% bootstrap), which includes the type species of *Oreocereus* plus the eight genera *Borzicactus* (here referred to *Cleistocactus*, according to Anderson, 2001 and Hunt, 2006), *Espositoa*, *Haageocereus*, *Matucana*, *Mila*, *Oroya*, *Pygmaeocereus*, and *Rauhocereus*, with a total of about 60 species (Hunt, 2006).

Next in the tree comes the *Denmoza* clade (Fig. 1B), which contains the monotypic *Denmoza rhodacantha*, *E. mirabilis* (syn. *Setiechinopsis*, monotypic as well), *E. leucantha*, and *Acanthocalycium*. *Acanthocalycium* was synonymized under *Echinopsis* s.l. by Hunt (2006), but was kept separate by Anderson (2001, 2005). All these taxa are endemic to northwestern Argentina, and their flowers are adapted to pollination by hummingbirds (*Denmoza*), bees (*Acanthocalycium*), or moths (*E. leucantha* and *E. mirabilis*, the latter unique in its short life-cycle, flowers closing before dawn, and autogamy; Kiesling and Ferrari, 2005).

The *Trichocereus* s.str. clade (Fig. 1B) is here represented by *Echinopsis pachanoi* and *E. lageniformis*, both columnar species characterized by few, blunt ribs, poor spination, and a moderate stem diameter (usually <20 cm). The type species of *Trichocereus*, *E. macrogona* [*Cereus macrogonus* Salm-Dyck; *Trichocereus macrogonus* (Salm-Dyck) Riccob.], is based on a cultivated specimen of unknown origin and appears related to *E. pachanoi* (Anderson, 2005; R. Kiesling, CONICET, Mendoza, Argentina, personal communication). The taxonomy is further complicated by *E. pachanoi*, a species long cultivated and hence widely distributed (“San Pedro cactus”).

The *Helianthocereus* clade (Fig. 1B) consists of species of mostly columnar to rarely globular growth with flowers adapted to pollination by bees or hawkmoths. Friedrich (1974) and Friedrich and Glätzle (1983), in a study of seed morphology for which they sampled ca. 20 of the species from this clade, found that all had seeds with an obliquely placed oval hilum surrounded by flat testa cells. Next in the tree comes the *E. bridgesii* clade (89% bootstrap support), which consists of five species from central Bolivia and northern Argentina with globular to short-columnar growth and flowers suggesting either bee or moth pollination. The recently described *Lobivia krahni-juckeri* (Diers, 2009) may also belong here. A final group worth discussing is the *Lobivia* clade (Fig. 1B), with a well-supported core clade (93% bootstrap support) and an unresolved group of early-branching species. Typical “lobivoid” species are small, mostly globular plants with short diurnal flowers. However, the *Lobivia* clade also includes species with long (>20 cm) white flowers adapted to pollination by sphingids (Schlumpfberger and Raguso, 2008; Schlumpfberger et al., 2009; Fig. 2A). Examples for those are *E. ancistrophora*, *E. obrepanda*, and *E. rojasii*.

In sum, the molecular data presented here conflict in large parts with previous taxonomic classifications of *Echinopsis* and its relatives (Anderson, 2001, 2005; Hunt, 2006). Morphological characters other than those traditionally used will have to be found to circumscribe natural taxonomic groups in the Trichocereeae, but large morphological differences may be difficult to find since the entire Trichocereinae/Cereinae clade is only 7.5–6.5 Myr old (Arakaki et al., 2011).

**Relative phylogenetic plasticity of growth habit and pollination syndromes**—In most of the clades revealed by our molecular data, growth form (globular vs. columnar) is phylogenetically conserved. The *Helianthocereus* clade (Fig. 1B), however, comprises globular species (*E. crassicaulis*, *E. lobivoides*), barrel cacti (*E. formosa* subsp. *korethroides*), species with thin, creeping or upright columns (*E. huascha*, *E. candicans*, *E. thelephona*), and large, robust columnar cacti (*E. tarijensis*, *E. formosa* subsp. *formosa* BOS460; Fig. 1B, 2C, 2D).

Pollination modes are evolutionary less conserved. Switches from bee to hawkmoth pollination or vice versa appear to be especially common. Examples are found in the *Lobivia*, *Helianthocereus* and *Echinopsis* s.s. clades (Fig. 1A, B). The finding of closely related species having different pollinators fits with population-level variation between bee and sphingid pollination, and nocturnal or diurnal flower opening (Schlumpfberger and Raguso, 2008; Schlumpfberger et al., 2009). A review of inferred evolutionary shifts between pollinators in genera of Cactaceae more generally is provided in Schlumpfberger (2012).

**The role of polyploidy in the evolution of the *Echinopsis* clade**—The 37 new chromosome counts reported here support the basic chromosome number of  $2x = 22$  inferred for Cactaceae (Remski, 1954; Pinkava et al., 1985). Tetraploidy is present in the *Lobivia* and *Helianthocereus* clades (Fig. 1A, B) and has also been reported from a few species not included in our tree, such as *E. spachiana* (likely part of our *Helianthocereus* clade) and *E. backebergii* subsp. *wrightiana* (*Lobivia* clade; Diers, 2008a; Table 3). Overall, the distribution of diploid and tetraploid (or higher) numbers on the phylogeny does not point to particularly frequent polyploidy events, compared for example with similarly sized clades in *Aristolochia*, *Passiflora*, *Carex*, and *Helianthus* (Ohi-toma et al., 2006; Hansen et al.,

2006; Hipp et al., 2007; Timme et al., 2007). It has been suggested that hybridization plays a major role in the evolution of Cactaceae (Rowley, 1994; Machado, 2008) and has also been hypothesized for *Echinopsis* (Friedrich, 1974; Font and Picca, 2001; Anderson, 2005) and related genera (Rowley, 1994). Observations in the field also suggest occasional hybridization, for example, between *E. atacamensis* subsp. *pasacana* × *E. huascha* subsp. *robusta*, *E. terscheckii* × *E. candidans*, *E. terscheckii* × *E. huascha*, and *E. ancistrophora* × *E. saltensis* (B. Schlumberger, unpublished data). However, at least the first cross in this list involves homoploidy (BS, unpublished data), and the relative scarcity of tetraploidy in the phylogeny (Fig. 1) thus does not necessarily reflect a rarity of hybridization.

**Conclusions**—The chloroplast DNA phylogeny presented here for 144 species and subspecies representing all major groups of *Echinopsis* sensu lato as well as all genera of Trichocereeae demonstrates the polyphyly of this genus as currently circumscribed. The phylogeny further reveals much convergent evolution in flower traits that relate to pollination modes (see Fig. 2A, B) and less convergent evolution in growth forms (but see Fig. 2C, D). There is no conspicuous role of genome doubling in the evolution of *Echinopsis* sensu lato. A new generic classification of the Trichocereeae now requires finding morphological characters sufficiently conservative for distinguishing larger groups of species. Seed morphology and growth form, perhaps in combination, seem promising starting points.
